

2(a)

The elements of  $arr1$  are copied up to  $length$  position  $n$  of  $arr3$  and the elements of  $arr2$  are copied to the remaining positions of  $arr3$ , starting from index  $length$ , while maintaining their original order. The sorting function is defined to recursively sort the input list  $para$ . The function divides the list  $para$  into two halves,  $a$  and  $b$ , using the midpoint ( $mid$ ). It recursively applies the sorting function to both halves,  $a$  and  $b$ . The function then merges the sorted halves  $a$  and  $b$  by comparing the elements from both halves and placing them in the resulting array  $arr$ . The time complexity of this is  $O(n \log n)$ , where  $n$  is the total number of elements in the merged list. This is because the algorithm recursively divides the input into two halves, performing a merge operation at each level, which takes  $O(n)$  time.
